Nephrotoxicity of Nickel Nanoparticles in Rat: Effect of Different Doses

Shang Z. Abdulqadir1 and Falah M. Aziz1

Abstract—The present investigation was dealt with the study of the effect of different doses of Nickel nanoparticles (NiNPs) (particle size equal to 20nm) on the kidney of rat. Intraperitoneal administration of NiNPs (0.5, 10, 20, 50 and 100mg/kg bw) was achieved for 28 days and the kidney samples were homogenized to estimate the level of malondialdehyde (MDA) as lipid peroxidation marker while creatinine was estimated in serum as well as studying the histopathological changes. Significant dose dependent elevation of MDA in kidney homogenate and a significant dose dependent increase of serum creatinine were detected. The most histopathological feature was the appearance of inflammatory aggregations of infiltrated leucocytes.

Keywords—Nickel nanoparticles, nephrotoxicity, MDA.

I. INTRODUCTION

Renal toxicity is one of the major concerns in preclinical toxicology studies. Renal toxicity can be a result of hemodynamic changes, direct injury to cells and tissue, inflammatory tissue injury, and/or obstruction of renal excretion. The kidney has important roles in plasma filtration and maintenance of metabolic homeostasis. Toxic effects on the kidney as a result of environmental toxicants can impair these kidney roles and induce changes in kidney function and structure [1].

Nanoparticles (NPs) are any materials or structures that have at dimension at 1–100 nm range [2]. With the development of nanotechnology, public concerns about the biological effects of NPs on the environment and human health have been raised [3]. NiNPs are widely used in hydrogen storages, chemical catalysts, ceramic capacitors, sensor and conductive paints, and nanomedicine over the past decade [4].

Another important sources of Ni particles uses which may bring them into environment are oil refineries and dust which may carry them [5]. Welding may generate a complex aerosol of incidental nanoparticles and cytotoxic metals, including nickel particles [6].

The majority of the published studies have assessed the cytotoxicity and genotoxicity of NPs on stable cell lines and in little degrees on laboratory animals. No doubt, in vitro experiments feature a number of advantages, in particular, relating to analysis of primary mechanisms of toxicity. However, any extrapolation of such experimental results to the whole mammalian organism is associated with a number of uncertainties and assumptions. Moreover, some important aspects of toxicology (in particular, toxicokinetics, dose-response relationships on organ and systemic levels, and the functioning of protective mechanisms) can generally be obtained only through experiments on a whole mammalian organism [7].

Previous studies had confirmed that Ni NPs might be more toxic than their fine particles even they may be more carcinogenic [8]-[9].

The major target organs for Ni compounds include liver, kidney, brain, lung and testes [10]. Ni was found to cause neurotoxicity, hepatotoxicity, nephrotoxicity, gene toxicity, reproductive toxicity [11]-[12]-[13]-[14].

The main mechanism suggested for the cell damage induced by NiNPs is by causing ROS elevation [15] which is considered to be a key mechanism for the cytotoxicity of nanomaterials [16]-[17]. NiNPs was also found to induce oxidative DNA damage [18], inflammation, cell degeneration [19], cell cycle arrest [20], cytogenetic alterations, oxidative stress and apoptosis [21].

The increased production of Ni-containing nanoparticles necessitates a thorough assessment of their toxicological properties [22].

The present investigation was aimed to focus more histological and cytological light on the nephrotoxicity of NiNPs using different doses of 20nm size nickel nanoparticles.

II. MATERIALS AND METHODS

A. Materials

Powdered 20nm nickel nanoparticles (NiNPs) were purchased from Sigma-Aldrich Co. (St Louis, MO, USA). All other chemicals were of laboratory grade and were used as received. All other necessary reagents were of analytical grade and were purchased from Sigma-Aldrich Co.

B. Preparation and Ultrasonication of NiNPs

Five different doses of NiNPs solutions were prepared in normal saline (5, 10, 20, 50 and 100mg/kg body weight) mmL. A stock suspension of NiNPs was prepared in normal saline (10mg/mL) by sonication for 30sec in ultrasonic homogenizer (model 150VT, manufactured by biologica, Ink, Manassas, Virginia, USA), the particle suspensions were kept on ice for 15sec and sonicated again on ice for a total of 3min at power.
of 400W. The NiNPs is vibrated for 2 min, immediately prior to the process of injection.

C. Experimental Design

Randomly 60 healthy mature female albino rats (Rattus norvegicus) weighing 200–220gm were divided into six groups, in group 1 (control) rats were injected intraperitoneally (i.p.) with normal saline, whereas the groups 2,3,4,5 and 6 (NiNPs-injected) rats were i.p. injected with ultrasonicated NiNPs (5,10,20,50 and 100 mg/kg body weight respectively). Injection of all groups were achieved for two days per a week for 28 days. At the end of administration, rats were sacrificed, and the kidney samples were removed for histological and biochemical studies.

D. Preparation of Kidney Homogenate

Kidney pieces of each rat were washed in ice-cold normal saline solution then homogenized in 20 mM phosphate buffer (pH = 7.4; tissue/ buffer ratio, 1/10 w/v) by handheld glass homogenizer. Kidney homogenates were centrifuged at 4,000 g at 4°C for 10 minutes (Beckman J2-21). The supernatants were collected and stored at -80°C until assayed.

E. Determination of Kidney Homogenate Malondialdehyde (MDA)

MDA level was estimated according to method of Kartha and Krishnamurthy [23]. One ml of the kidney homogenates were added to 20% trichloroacetic acid. After centrifugation for 10 minutes, 2 mls of supernatant were taken in a test tube, 2mls of 0.7% thiobarbituric acid were added to each tube and kept in boiling water bath for 20 minutes. The development of pink color was measured at 535 nm and the value of MDA concentration was expressed by MDA(nmol/g of tissue).

F. Blood Collection

At the end of the treatment period, blood samples were collected from all anesthetized rats of six groups through cardiac puncture in which the collected blood samples were immediately placed into gel tube for serum collection, later cardiac puncture in which the collected blood samples were centrifuged (Hettich D-78532/Germany) at 3000 rpm for 10 minutes (Beckman J2-21). The sera were stored at -80°C (Sanyo – Ultra – Low Temperature, Japan) for creatinine estimation.

G. Estimation of Creatinine

Serum creatinine was determined spectrophotometrically (Cobas c311 Hitachi-Japan) using BIOLABO kit(France). Creatinine reacts with picrate to form a colored complex in alkaline solution; the intensity of the color is proportional to the concentration of the creatinine. Absorbency of samples were read at 500 nm.

H. Histological Techniques

Kidney pieces were fixed in 10% buffered formaldehyde for 24 hours, followed by dehydration using a series of ethanol in ascending concentrations (50%, 70%, 95% and 100%), then immersed in xylene, infiltrated embedded in paraffin wax. Five micrometer thick sections were obtained using rotary microtome (Bright, MIC) and stained by hematoxylin and eosin (H&E) [24].

I. Electron Microscopy

Scanning electron microscopy was used for photographing the NiNPs after coating with platinum.

J. Statistical Analysis

All data are expressed as means ± standard error (M ± SE) and statistical analysis was carried out using statistically available software (SPSS version 22). One-way analysis of variance (ANOVA) was performed to test for significance of a treatment effect followed by Duncan’s multiple range comparison tests for comparisons between the groups. P values ≤ 0.05 were considered significant.

III. RESULTS AND DISCUSSION

The present investigation which dealt with the study of the effect of different doses of 20nm sized NiNPs (as appeared in Fig 1A viewed under scanning electron microscopy) on the kidney of rats, revealed a significant (≤ 0.05) dose dependent increase in the malondialdehyde level (Fig 1B), is the final product of lipid peroxidation process [25] and is still routinely used as a marker for oxidative stress induced by different toxicants [26]. Several works conclusions have agreed about the mechanism of NiNPs in inducing the toxicity in vivo [19] and in vitro [22]-[18] which is the inducting oxidative stress through elevating the levels of reactive oxygen species (ROS).

In the present investigation, NiNPs have caused a significant (P≤0.05) dose dependent elevation of serum creatinine in comparison to the control (Fig.2). This may be related to the NiNPs accumulated in the renal tissues, that enhanced the partial or full renal failure leading to decrease the efficiency of the kidney, and in turn hinder and/or disturb the excretion of the two metabolites from the circulation via the urine [27].

The high levels of creatinine could reflect the abnormal glomerular filtration rate due to the metals accumulation in kidney [28]. Among literatures, the results with respect to creatinine levels in response to NiNPs exposure were conflicting. In acute intravenous injection, no changes in crea-
-tinine level was observed [8], whereas after 3, 7, 14 and 28 days post-injection of NiNP, levels of creatinine were significantly higher than the corresponding controls, and positively correlated with the experimental periods [8]. Recently, rats were exposed to acute (125, 250, and 500 mg/kg) doses of NiO NPs in female Wistar rats and many nephritic biochemical changes have been recorded [29].

Histologically, the present investigation showed several changes in the structure of the kidney and the most important features were the appearance of inflammatory infiltrated leucocytes (Fig.3) in approximately dose dependent pattern. The inflammatory cells which were mainly lymphocytes were located in the interstitial spaces between the kidney tubules, around blood vessels and around the glomeruli (Fig.4). Other morphological changes included dilatation of the kidney tubules and degeneration of kidney tubules epithelial cells. Recently, NiONPs were taken up by kidney cell line and induced dose-dependent DNA damage and apoptotic/nephritic effects [18]. Reference [30] studied the effects intraperitoneal injection and aspiration effects of nickel nanowire with diameter of 200 nm and length of more than 20 μm in mice and found out that they caused strong inflammation in mouse peritoneal cavity and lung respectively, in a dose-dependent manner. Nanoparticles were also found to up-regulate the transcription of various pro-inflammatory genes, including tumor necrosis factor-α and IL (interleukins)-1, IL-6 and IL-8, by activating nuclear factor-kappa B (NF-κB) signaling. These sequential molecular and cellular events are known to cause oxidative stress, followed by severe cellular genotoxicity and then programmed cell death [31]. Those previous results that concerning the effect of nanoparticles on interleukins may explain the present nephrotoxic results such as inflammation. Dose dependent nephrotoxicity effect of NiNPs may be related to the dose dependent accumulation of these particles in the kidney throughout the 28 days of exposure [32].
