Abstract: *The possibility to limit and manipulate photons at nanometer scales attracted a lot of interest for exciting applications from subwavelength in biosensors and optoelectronics devices, the sensor optical properties, however; are complex due to two resonances through propagating and localized surface plasmons. The optical properties of surface plasmons(SPs) at the resonant wavelength is depending on the   geometrical nanostructure of materials. In this articles, we used different geometry of nanoholes array, 4 and 9 nanoholes array in a metallic film gold nanoparticles with different thickness (20,50,100) nm on SiO2 substrate with refractive index 1.46, we designed two different geometries; 4- holes: hole radius r1=200 nm, period p1=600 nm; and 9- holes : r2=100 nm, period p2=300 nm.*

Transmission and reflection spectrum   have been calculated and simulated by FDTD Lumerical program. From results are observed the effect of thickness is interesting, transmission is increased at (t=20nm) for two arrays. Furthermore, the number of hole and its area has an influence on optical transmission and other parameters (E, H ,Ref) which are characteristics of design of metallic nanostructure.
We can see that there is a peak value of the wavelength at 519 nm approximately to 73% strong light transmission with 4-NHA in the other hand wavelength of 519 nm transmission is 45%   with 9-NHA. strong light transmission is hopeful for many applications(Biosensors devices).

Keywords: *Plasmonics .Optical transmission . Biosensors . FDTD. Localized surface plasmons. Nanoholes array. Geometrical parameters.*

1-Introduction

Surface Plasmons (**S**Ps) are collective oscillations of free electrons which are excited by light or photon (from visible to IR) [1]. Firstly SPP involves on one side the coherent oscillation of the conduction electrons at the interface inside the metal, and on the other side the propagation of an electromagnetic wave along the surface, inside the dielectric as equations (1&2) as shown in figure (1) ,we find the values of wave number and Surface Plasmon frequency ω_{sp} as shown in figure (2) ,as [2,3]

$$\beta = \frac{\omega}{c}\sqrt{\frac{\varepsilon_m \varepsilon_d}{\varepsilon_m + \varepsilon_d}} \tag{1}$$

$$\omega_{sp} = \frac{\omega_p}{\sqrt{1+\varepsilon_d}} \tag{2}$$

Secondly , Localized surface Plasmons (LSPs) are non-propagating excitations of the conduction electrons of metallic nanostructures coupled to the electromagnetic field. LSPs are excited at certain resonance frequencies (or resonance wavelengths, typically in the visible region), resulting in scattering and absorption at these frequencies for example optical nanoantennas [4] A Plasmon is a quantized plasma oscillation, and the motion of the collective oscillation can rightly support electromagnetic (EM) waves at optical frequencies. The Lorentz-Drude model equation of motion is:-

$$\vec{F} = m\vec{a} = m \frac{d^2x}{dt^2} = -qE \tag{3}$$

The dipole moment per unit volume, is:-

$$P = -nqx = -\frac{nq^2}{m\omega^2}E \tag{4}$$

$$\omega_p^2 = \frac{nq^2}{\varepsilon_o m} \tag{5}$$

Nanoholes array display high transmission due to the matching between the incident light and SPRs through the holes at the surface of the metallic film [5,6]. Thin metallic films patterned with a nanoholes array also support surface plasmons excitation due grating coupling, and the resonance condition for Plasmon excitation depends on refractive index of the surrounding medium [7].
EOT (An extraordinary optical transmission) supported by a subwavelength periodic nanoholes array patterned on thin film of metal [8,9].
Some geometrical coefficients like a thickness of metal and substrate; the hole diameter also the number of periodic holes and metal properties can effect on EOT spectra because the surface plasmons that will be excited by incident light is affected by changing the size of hole and it have been confirmed that any change in the size of the holes lead to a small variations in transmission efficiency and peak positions [10-14]. Je Hong provided that the transmission characteristics is a function of film thickness of metallic hole array samples which is prepared with different hole periodicity, size and shape on a silica substrate and shows highly transmission efficiency at small thickness of gold metal [15,16]. Plasmonic nanostructures have been extensively investigated both for scientific interest in their unique optical properties and for practical applications, such as optoelectronic devices, sensors, biomedical treatment; and so on [17,18].
Since plasmonic sensing requires simply an optical transmission spectrum, or only the transmitted intensity at one or a few wavelengths [19].
In this study we presented the differences between two holes arrays of 4 and 9 holes for different thickness (20,50,100) nm to characterize the optical properties for surface plasmons metals and to determined from these parameters the affects geometry and shape on sensors applications and optoelectronic devices .

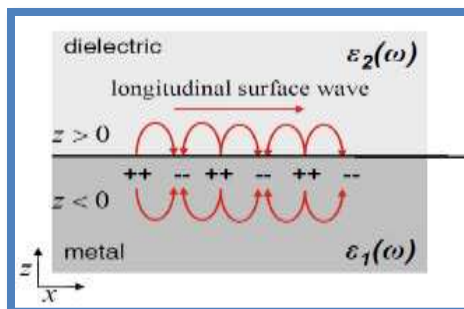

Fig.1 "Schematic of a Surface Plasma wave (SPPs) at a metal-dielectric interface"[3].

Fig 2. "How to find the frequency surface plasmons at air and dielectric " [2].

2. Method of Analysis

Two designs of nanoholes array (NHA) of 4 and 9 nanoholes which they patterned with periodic array of nanoholes with radius r_1, r_2 for 4 and 9 respectively in thin film of gold in different thickness for each design (20, 50, 100) nm which based on SiO_2 substrate with refractive index (n=1.46) and thickness fixed in two cases (t= 950 nm).

These designs are performed as 2×2 array with P_1=600nm and r_1=200nm in the other hand 3×3 array with P_2=600nmand r_2=200nm, with consideration that these holes are patterned on the same direction of a sample Au/SiO$_2$ as shown in figure (3a-b).

In this work we use FDTD method that deals with Maxwell's equations in surface plasmons ,this technique is helpful to analyze the interaction of incident light with structure (NHAs) and by Durde model is computed the noble metals which fits the literature data from Palik [20]. From these arrays the transmission and reflection have been calculated by such program and considered magnetic field intensity (H) and electric field intensity (E) [21]. In addition, there was researches about different geometry and shapes like square and hexagonal lattice, grating and grid thin film of metal to develop biological sensing performance .

3. Results and discussion

In this work, we used FDTD by Lumerical solution Inc. to design a simulation of nanoholes array of 4 and 9-NHA in different periodic array and diameters of holes patterned on thin film of gold based on silicon dioxide, SiO$_2$ substrate (n=1.46) by this program the interaction of incident light wavelength (λ= 350-750) nm with nanoholes array structure is analyzed . From the simulation FTDT and design of NHA , the asymmetric and anti symmetric boundary conditions were considered for the x- and y-directions, respectively, and we study the transmission properties at normal incident of electromagnetic wave through the sub wavelength nanoholes structure. For 4-NHA, the FDTD simulations showing that transmission efficiency reached about 73% in visible.
Fig (3) "Field Distributions for H and E of 4-NHA with Varying Thickness of Au: (20, 50, 100) Nm"

From fig.(3) the E distributions for 4-holes array with period P_1=600 nm are shown in fig.(3a-c), we can see that E at t=50 nm is larger than the other thickness (20,100) nm corresponding to the two modes of transmission in fig.(5c) to determined the near field enhancement.

In the other hand, in fig.(3d-f) we can see that the H distributions have a maximum value at t=50nmdepending on the two modes of reflection at t=50 nm in fig.(5e).

Furthermore, these field enhancements are mainly located within the holes. This is highly desirable for biosensing devices as it rises the overlap of the analyses with the electromagnetic field(E and H) inside the hole by effective the positions of the surface plasmons.

Fig 4. "Field Distributions for H and E Of 9-NHA with Varying Thickness of Au: (20, 50, 100) Nm"

From fig.(4) the E distributions for 9-NHA with period P_1=300 nm are shown in fig.(4a-c),we can see that E at t=100 nm is larger than the other thickness (20,50)nm corresponding to the two modes of transmission in fig(6e) to determined the near field enhancement. In the other hand, in fig.(4d-f) we can see that the H distributions have a maximum value at t=100 nm depending on the two modes of reflection at t=100 nm in fig.(6d).

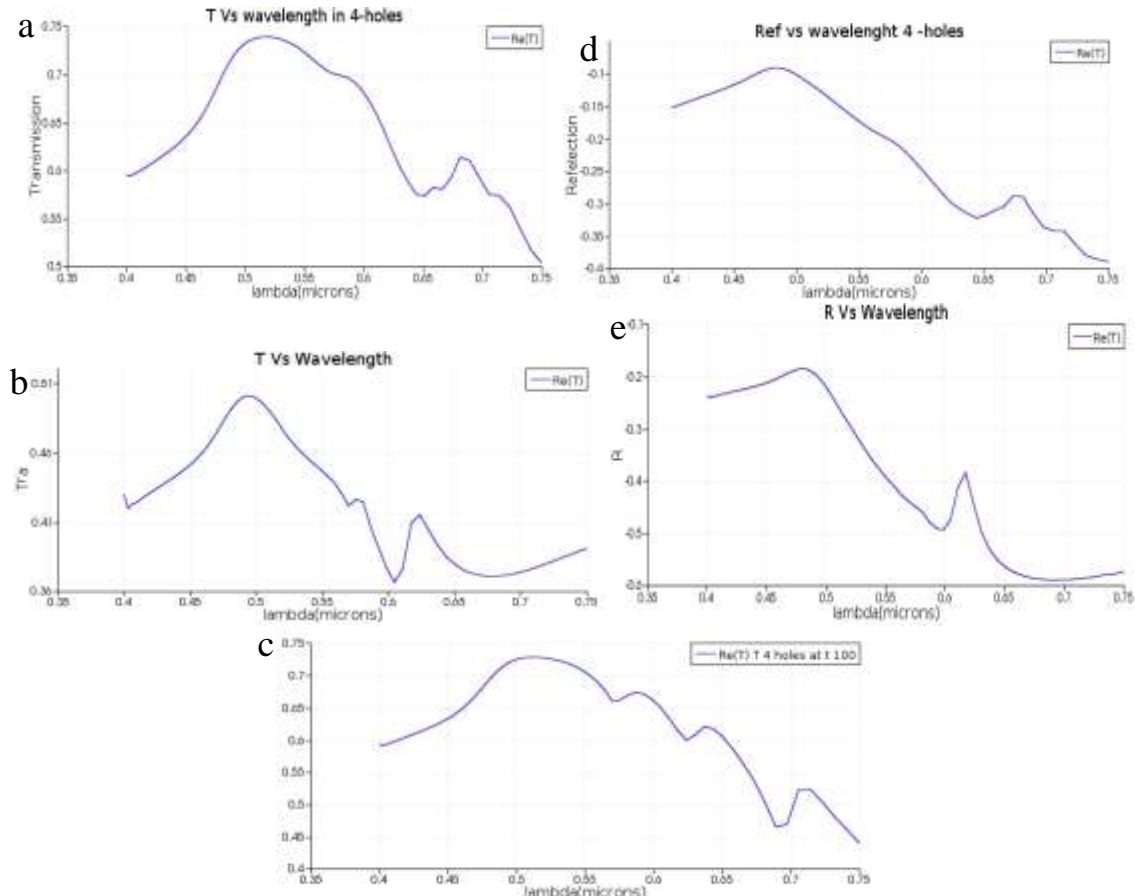

Fig 5. A, B And C " Transmission; D and E Reflection Resonance for 4-NHA At T(Au)=(20, 50, 100) Nm"
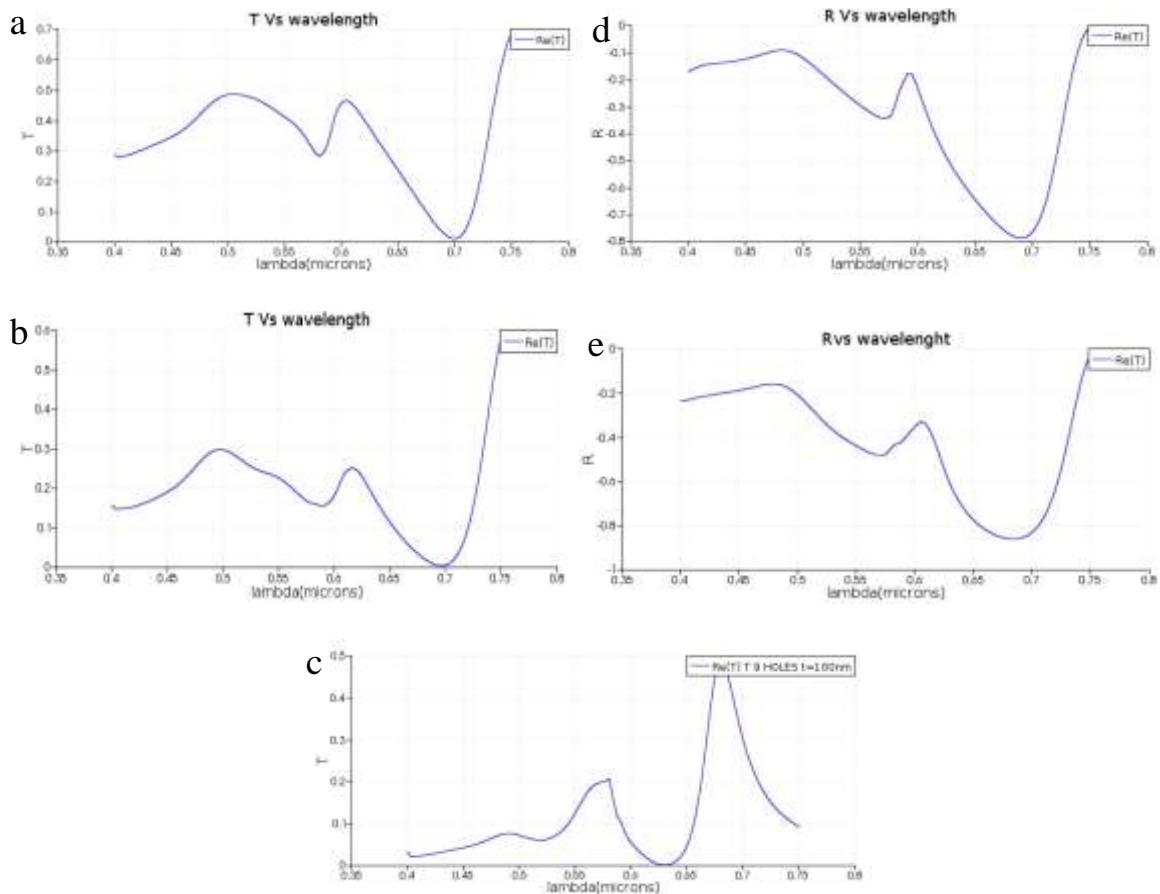

Fig 6. A, B And C " Transmission; D and E Reflection Resonance for 9-NHA at T(Au)=(20, 50, 100) Nm"

We can see that there is a peak value of the wavelength at 519 nm approximately to 73% strong light transmission with 4-NHA in fig.(5a), in the other hand wavelength of 519 nm transmission is 45%   with 9-NHA in fig.(6a). Strong light transmission is hopeful for using in biological devices with Au/ SiO_2 interface .

4. Conclusions

In this article, we studied the important parameters that effect on the performance optical properties in NHA and surface plasmons like, the noble metals with dielectric layers; different geometrical of NHA with varying thickness and methods of excitation SPs.

From the results are observed the effect of   holes depth, with consideration the number of holes and P have an influence on SPs interface, transmission is increased at (t=20nm) for two arrays but at 4-holes is greater than 9-holes array, that leads   to   which one is suitable for biosensors. With each thickness It is challenging to fabricate the nanoholes NHAs structure because the metal film is too thick for a clean liftoff (typically≥100 nm for Au and ≥300 nm for Ag to make the film "optically thick").
